# Transformation of Recursive Partitionings during the Induction of Hybrid Grammars 

Johann Seltmann

May 28, 2017

## 1 Introduction

In natural language processing, syntactical structures are often represented as trees. However, in some languages, it is possible to splice a syntactical structure and put the words belonging to it at separate positions in the sentence. This phenomenon is called discontinuity. A classical parse tree cannot represent a discontinuous structure.

Example 1.1. In the German sentence "Das Buch gab sie ihm" ("She gave him the book.", literally "The book gave she him"), the verb phrase "gab ihm das Buch" is broken by the subject of the sentence. The tree that represents the syntactic structure of the sentence does not represent that fact:

Nederhof and Vogler [7] introduce the concepts of hybrid trees and hybrid grammars which can represent discontinuity by coupling a tree and a string.

Example 1.2. A hybrid tree that represents both the sentence from Example 1.1 with its correct word order and its parse tree.

Gebhardt et al. [5] formally introduce algorithms for the induction of hybrid grammars using recursive partitionings. The properties of the recursive partitioning influence the properties of the resulting grammar. Therefore, they also introduce an algorithm for the transformation of recursive partitionings in order to induce a grammar with more desirable properties. In this thesis, I explore different instances of that algorithm and how these instances influence the resulting hybrid grammar.

In Section 2 I will give basic notations and definitions. In Section 3 I will show the transformation algorithm from [5]. Then I will give an overview of my implementation (Section 4), which is based on the implementation by Gebhardt et al. [5]. Finally, I will give my experimental results in Section 5.

## 2 Preliminaries

Let $\mathbb{N}=\{0,1,2, \ldots\}$. For each $k \in \mathbb{N}$, let $[k]=\{1,2, \ldots, k\}$ and $[k]_{0}=[k] \cup\{0\}$.
A ranked alphabet is a tuple $(\Sigma, r k)$, where $\Sigma$ is a finite set and $r k$ is a mapping $r k: \Sigma \rightarrow \mathbb{N}$. Instead of $(\Sigma, r k)$, we will just write $\Sigma$. Let $k \in \mathbb{N}$. Then $\Sigma^{(k)}$ is the set of all $\sigma \in \Sigma$ with $r k(\sigma)=k$. An alphabet is a ranked alphabet $\Sigma$, where for all $\sigma \in \Sigma, r k(\sigma)=0$.

We define $X=\left\{x_{1}, x_{2}, \ldots\right\}$ as a set of variables. For all $k>0 X_{k}=$ $\left\{x_{1}, \ldots, x_{k}\right\}$.

Let $\Sigma$ be a ranked alphabet, $Y \subseteq X$. The set of all trees over $\Sigma$ and $Y$, denoted $T_{\Sigma}(Y)$, is the smallest set $S$ such that,
i) $Y \subseteq S$, and
ii) for all $k \in \mathbb{N}, \sigma \in \Sigma^{(k)}$ and $\xi_{1}, \ldots, \xi_{k} \in S, \sigma\left(\xi_{1}, \ldots, \xi_{k}\right) \in S$.

Instead of $T_{\Sigma}(\emptyset)$, we will write $T_{\Sigma}$.

Let $k \in \mathbb{N}, \Sigma$ a ranked alphabet, $\sigma \in \Sigma^{(k)}, Y \subseteq X$, and $\xi, \xi_{1}, \ldots, \xi_{k} \in T_{\Sigma}(Y)$. Then the set of positions of $\xi$ is defined as

$$
\operatorname{pos}(\xi) \quad=\quad \begin{cases}\{\varepsilon\} & \text { if } \xi \in Y, \text { and } \\ \{\varepsilon\} \cup \bigcup_{i=1}^{k}\left\{i w \mid w \in \operatorname{pos}\left(\xi_{i}\right)\right\} & \text { if } \xi=\sigma\left(\xi_{1}, \ldots, \xi_{k}\right)\end{cases}
$$

I will also call a position of $\xi$ a node of $\xi$. Let $p, q \in \operatorname{pos}(\xi) . q$ is a child of $p$ if there is an $i \in \mathbb{N}$ such that $q=p i$. Then $p$ is called the parent of $q$. A leaf is a node of $\xi$ that has no children. Let $p \in \operatorname{pos}(\xi)$. The subtree of $\xi$ at position $p$, denoted by $\left.\xi\right|_{p}$, is defined recursively as

$$
\left.\xi\right|_{p}= \begin{cases}\xi & \text { if } p=\varepsilon, \text { and } \\ \left.\xi_{i}\right|_{w} & \text { if for some } i \in[k] \\ & \text { and } w \in \operatorname{pos}\left(\xi_{i}\right), p=i w \text { and } \xi=\sigma\left(\xi_{1}, \ldots, \xi_{k}\right)\end{cases}
$$

The label of $\xi$ at position $p$, denoted by $\xi(p)$, is defined as

$$
\xi(p)= \begin{cases}\sigma & \text { if } p=\varepsilon \text { and } \xi=\sigma\left(\xi_{1}, \ldots, \xi_{k}\right), \text { and } \\ \left.\xi_{i}\right|_{w} & \text { if for some } i \in[k] \\ & \text { and } w \in \operatorname{pos}\left(\xi_{i}\right), p=i w \text { and } \xi=\sigma\left(\xi_{1}, \ldots, \xi_{k}\right)\end{cases}
$$

Let $Y \subseteq X, \xi=\sigma\left(\xi_{1}, \ldots, \xi_{k}\right), \zeta \in T_{\Sigma}(Y)$, and $p \in \operatorname{pos}(\xi)$. Then the substitution of $\xi$ at position $\zeta$ with $\zeta$, denoted by $\xi[\zeta]_{p}$, is defined as

$$
\xi[\zeta]_{p}= \begin{cases}\zeta & \text { if } p=\varepsilon, \text { and } \\ \sigma\left(\xi_{1}, \ldots, \xi_{j-1}, \xi_{j}[\zeta]_{q}, \xi_{j+1}, \ldots \xi_{k}\right) & \text { if for some } j \in[k] \\ & \text { and } q \in \operatorname{pos}\left(\xi_{j}\right), p=j q\end{cases}
$$

Hybrid trees are introduced by Nederhof and Vogler [7]. We will be using a notation without s-terms. Let $\Sigma$ be a ranked alphabet and $\Gamma \subseteq \Sigma$. A hybrid tree over $(\Gamma, \Sigma)$ is a tuple $h=\left(\xi, \leq_{\xi}\right)$ where $\xi \in T_{\Sigma}$ and $\leq_{\xi}$ is a total order on $\operatorname{pos}_{\Gamma}(\xi)=\{p \in \operatorname{pos}(\xi) \mid \xi(p) \in \Gamma\}$. A hybrid tree $h$ is a dependency structure if $\Gamma=\Sigma$. Let $\operatorname{pos}_{\Gamma}(\xi)=\left\{p_{1}, \ldots, p_{n}\right\}$ with $p_{i} \leq_{\xi} p_{i+1}$ for $i \in[n-1]$. Then $\operatorname{str}(h)=\xi\left(p_{1}\right) \ldots \xi\left(p_{n}\right)$.

Example 2.1. This is an example for a hybrid tree $h=\left(\xi, \leq_{\xi}\right)$ where $\xi$ is the tree from Example 1.1 and $\leq_{\xi}$ is represented by the string "Das Buch gab sie ihm" at the bottom.

### 2.1 Hybrid grammars

Let $\Sigma$ be a ranked alphabet and $\Gamma \subseteq \Sigma$. A hybrid grammar over $(\Gamma, \Sigma)$ combines a tree grammar and a string grammar such that for each tree $\xi$ produced by the tree grammar, the string grammar produces a string $s$ with $s=\operatorname{str}(h)$ for a hybrid tree $h=\left(\xi, \leq_{\xi}\right)$.

Gebhardt et al. [5] describe several possible combinations of string and tree grammars for hybrid grammars. We will be focusing on hybrid grammars, that combine linear context-free rewriting systems (LCFRS) and simple definite clause programs ( sDCP ), here, since that is the type of hybrid grammar used in the implementation. In order to define this special kind of hybrid grammar, I first recall the definitions of LCFRS and sDCP.

### 2.1.1 Linear context-free rewriting systems

LCFRS were first introduced by Vijay-Shanker et al. [10]. We will be using the notation of [5] here.

A linear context-free rewriting system (LCFRS) is a tuple $G=(N, \Sigma, S, R)$ where

- $N$ is a ranked alphabet of nonterminals,
- $\Sigma$ is a ranked alphabet of terminals with $\Sigma \cap N=\emptyset$ and for all $\sigma \in \Sigma$ $r k(\sigma)=0$,
- $S \in N^{(1)}$ is the initial nonterminal, and
- $R$ is a finite set of rules, specified in the following.

Each rule is of the form

$$
A_{0}\left(s_{1}, \ldots, s_{k_{0}}\right) \rightarrow A_{1}\left(x_{1}, \ldots, x_{m_{1}}\right), A_{2}\left(x_{m_{1}+1}, \ldots, x_{m_{2}}\right), \ldots, A_{n}\left(x_{m_{n-1}+1}, \ldots, x_{m_{n}}\right)
$$

where $n \in \mathbb{N}, i \in[n]_{0}, k_{i}=r k\left(A_{i}\right), m_{i}=\sum_{i^{\prime} \in[i]} k_{i^{\prime}}, j \in\left[k_{0}\right], s_{j} \in\left(\Sigma \cup\left(X_{m_{n}}\right)\right)^{*}$, and for each $l \in\left[m_{n}\right], x_{l}$ occurs exactly once in $s_{1}, \ldots, s_{k_{0}}$.

Let $m \in \mathbb{N}$ and $\rho \in R$ such that $\rho$ contains $m$ variables. A rule instance of $\rho$ can be obtained by choosing an $r_{i} \in \Sigma^{*}$ for each $i \in[m]$ and replacing both occurences of $x_{i}$ in $\rho$ with $r_{i}$.

Let $s_{1}, s_{2} \in(\Sigma \cup X)^{*}, \rho \in R$, and $t \rightarrow r$ be a rule instance of $\rho$. Then the derivation relation is defined as $s_{1} \cdot t \cdot s_{2} \Rightarrow{ }_{G}^{\rho} s_{1} \cdot r \cdot s_{2}$.

The string language produced by an LCRFS $G=(N, \Sigma, S, R)$ is $L(G)=$ $\left\{s \in \Sigma^{*} \mid S(s) \Rightarrow_{G}^{*} \varepsilon\right\}$.

Let $A \in N$. We call $r k(A)$ the fanout of $A$. The fanout of the $L C F R S G$ is the maximal fanout of its nonterminals.
Example 2.2. The following LCFRS G produces the string "Das Buch gab sie ihm". $G=(N, \Sigma, S, R)$, where

- $N=\{S, N P, V P, V, D e t, N\}$ with $r k(V P)=2$ and for all $A \in N \backslash\{V P\}$ : $r k(A)=1$,
- $\Sigma=\{$ Buch, sie, ihm, gab, Das $\}$, and
- $R=\left\{\rho_{1}, \ldots, \rho_{8}\right\}$ as specified in the following.

$$
\begin{aligned}
& \rho_{1}=S\left(x_{2} x_{1} x_{3}\right) \rightarrow N P\left(x_{1}\right) V P\left(x_{2}, x_{3}\right) \\
& \rho_{2}=V P\left(x_{3} x_{1}, x_{2}\right) \rightarrow V\left(x_{1}\right) N P\left(x_{2}\right) N P\left(x_{3}\right) \\
& \rho_{3}=N P\left(x_{1} x_{2}\right) \rightarrow \operatorname{Det}\left(x_{1}\right) N\left(x_{2}\right) \\
& \rho_{4}=N P(\text { sie }) \rightarrow \varepsilon \\
& \rho_{5}=V(\text { gab }) \rightarrow \varepsilon \\
& \rho_{6}=\operatorname{Det}(\text { Das }) \rightarrow \varepsilon \\
& \rho_{7}=N(\text { Buch }) \rightarrow \varepsilon \\
& \rho_{8}=N P(\text { ihm }) \rightarrow \varepsilon
\end{aligned}
$$

The string can be derived as follows:

$$
\begin{aligned}
& S(\text { Das Buch gab sie ihm }) \\
& \Rightarrow_{G}^{\rho_{1}} N P(\text { sie }) V P(\text { Das Buch gab, ihm }) \\
& \Rightarrow_{G}^{\rho_{4}} V P(\text { Das Buch gab, ihm }) \\
& \Rightarrow_{G}^{\rho_{2}} V(\text { gab }) N P(\text { Das Buch }) N P(\text { ihm }) \\
& \Rightarrow_{G}^{\rho_{5}} N P(\text { Das Buch }) N P(\text { ihm }) \\
& \Rightarrow_{G}^{\rho_{8}} N P(\text { Das Buch }) \\
& \Rightarrow_{G}^{\rho_{3}} \operatorname{Det(\text {Das})N(\text {Buch})} \\
& \Rightarrow_{G}^{\rho_{6}} N(\text { Buch }) \\
& \Rightarrow{ }_{G}^{\rho_{7}} \varepsilon
\end{aligned}
$$

### 2.1.2 Simple definite clause programs

Definite clause programs are introduced in [3]. We will use a notation based on the one in [7].

A simple definite clause program ( sDCP ) is a tuple $G=(N, \Sigma, S, P)$ where

- $N$ is a ranked alphabet of nonterminals,
- $\Sigma$ is a ranked alphabet of terminals,
- $S \in N$ is the initial nonterminal, and
- $P$ is a set of rules, described in the following.

Each $A \in N$ is assigned a number of synthesized arguments (its s-rank, denoted by $s-r k(A)$ ) and a number of inherited arguments (its i-rank, denoted by $i-r k(A)$ ) where $r k(A)=s-r k(A)+i-r k(A)$. For the initial nonterminal we demand $r k(S)=s-r k(S)=1$. Each rule has the form

$$
\begin{aligned}
& A_{0}\left(x_{1}^{(0)}, \ldots, x_{k_{0}}^{(0)}, s_{1}^{(0)}, \ldots, s_{k_{0}^{\prime}}^{(0)}\right) \rightarrow \\
& A_{1}\left(x_{1}^{(1)}, \ldots, x_{k_{1}}^{(1)}, s_{1}^{(1)}, \ldots, s_{k_{1}^{\prime}}^{(1)}\right) \ldots A_{n}\left(x_{1}^{(n)}, \ldots, x_{k_{n}}^{(n)}, s_{1}^{(n)}, \ldots, s_{k_{n}^{\prime}}^{(n)}\right)
\end{aligned}
$$

where $n \in \mathbb{N}, k_{i}=r k\left(A_{i}\right)\left(i \in[n]_{0}\right), m=\sum_{i \in[n]_{0}} k_{i}, \bigcup_{j=0}^{n} \bigcup_{i=1}^{k_{j}} x_{i}^{(j)}=X_{m}$, $s_{1}^{(i)}, \ldots, s_{k_{i}^{\prime}}^{(i)} \in T_{\Sigma}\left(X_{m}\right)\left(i \in[n]_{0}\right)$ such that all $s_{j}^{(i)}\left(i \in[n]_{0}, j \in\left[k_{i}^{\prime}\right]\right)$ together contain each variable in $X_{m}$ exactly once.

Let $\rho \in P$ and $m \in \mathbb{N}$ such that $\rho$ contains $m$ variables. A rule instance of $\rho$ can be obtained by choosing an $r_{i} \in T_{\Sigma}$ for each variable $x_{i}(i \in[m])$ and replacing all occurences of $x_{i}$ with $r_{i}$.

Let $m \in \mathbb{N}, s_{1}, s_{2} \in T_{\Sigma}\left(X_{m}\right), \rho \in P$, and $t \rightarrow r$ a rule instance of $\rho$. Then the derivation relation can be defined as $s_{1} t s_{2} \Rightarrow{ }_{G}^{\rho} s_{1} r s_{2}$

The language accepted by an sDCP $G$ is $L(G)=\left\{s \in T_{\Sigma} \mid s \Rightarrow_{G}^{*} \varepsilon\right\}$.
Example 2.3. The following sDCP $G$ accepts the tree from Example 1.1. $G=(N, \Sigma, S, P)$, where

- $N=\{S, N P, V P, V, D e t, N\}$ where for all $A \in N: r k(A)=1$,
- $\Sigma=\{\mathbf{S}, \mathbf{N P}, \mathbf{V P}, \mathbf{V}$, Det, $\mathbf{N}$, Das, Buch, gab, sie, ihm $\}$, and
- $P=\left\{\rho_{1}, \ldots, \rho_{8}\right\}$, as specified in the following.

$$
\begin{aligned}
& \rho_{1}=S\left(\mathbf{S}\left(x_{1} x_{2}\right)\right) \rightarrow N P\left(x_{1}\right) V P\left(x_{2}\right) \\
& \rho_{2}=V P\left(\mathbf{V P}\left(x_{1} x_{2} x_{3}\right)\right) \rightarrow V\left(x_{1}\right) N P\left(x_{2}\right) N P\left(x_{3}\right) \\
& \rho_{3}=N P\left(\mathbf{N P}\left(x_{1} x_{2}\right)\right) \rightarrow \operatorname{Det}\left(x_{1}\right) N\left(x_{2}\right) \\
& \rho_{4}=N P(\mathbf{N P}(\text { sie })) \rightarrow \varepsilon
\end{aligned}
$$

$$
\begin{aligned}
& \rho_{5}=V(\mathbf{V}(\mathbf{g a b})) \rightarrow \varepsilon \\
& \rho_{6}=\operatorname{Det}(\mathbf{D e t}(\mathbf{D a s})) \rightarrow \varepsilon \\
& \rho_{7}=N(\mathbf{N}(\mathbf{B u c h})) \rightarrow \varepsilon \\
& \rho_{8}=N P(\mathbf{N P}(\mathbf{i h m})) \rightarrow \varepsilon
\end{aligned}
$$

The tree can be derived as follows:

$$
\begin{aligned}
& S(\mathbf{S}(\mathbf{N P}(\mathbf{s i e}), \mathbf{V P}(\mathbf{V}(\text { gab }), \mathbf{N P}(\mathbf{i h m}), \mathbf{N P}(\mathbf{D e t}(\text { Das }), \mathbf{N}(\text { Buch }))))) \\
& \Rightarrow_{G}^{\rho_{1}} N P(\mathbf{N P}(\text { sie })), V P(\mathbf{V P}(\mathbf{V}(\text { gab }), \mathbf{N P}(\mathbf{i h m}), \mathbf{N P}(\operatorname{Det}(\text { Das }), \mathbf{N}(\text { Buch })))) \\
& \Rightarrow_{G}^{\rho_{4}} V P(\mathbf{V P}(\mathbf{V}(\text { gab }), \mathbf{N P}(\mathbf{i h m}), \mathbf{N P}(\mathbf{D e t}(\text { Das }), \mathbf{N}(\text { Buch })))) \\
& \Rightarrow_{G}^{\rho_{2}} V(\mathbf{V}(\mathbf{g a b})) N P(\mathbf{N P}(\mathbf{i h m})) N P(\mathbf{N P}(\mathbf{D e t}(\text { Das }), \mathbf{N}(\text { Buch }))) \\
& \Rightarrow_{G}^{\rho_{5}} N P(\mathbf{N P}(\mathbf{i h m})) N P(\mathbf{N P}(\operatorname{Det}(\mathbf{D a s}), \mathbf{N}(\text { Buch }))) \\
& \Rightarrow_{G}^{\rho_{8}} N P(\mathbf{N P}(\mathbf{D e t}(\mathbf{D a s}), \mathbf{N}(\text { Buch }))) \\
& \Rightarrow_{G}^{\rho_{3}} \operatorname{Det}(\mathbf{D e t}(\mathbf{D a s})) N(\mathbf{N}(\mathbf{B u c h})) \\
& \Rightarrow_{G}^{\rho_{6}} N(\mathbf{N}(\mathbf{B u c h})) \\
& \Rightarrow{ }_{G}^{\rho_{7}} \varepsilon
\end{aligned}
$$

### 2.1.3 LCFRS/sDCP hybrid grammars

Hybrid grammars are introduced by [7]. Here, we are using the notation of [5]
In order to link an LCFRS and an sDCP together we index the terminals and nonterminals of both grammars. Let $\Omega$ be a ranked alphabet. The ranked
 $r k_{\Omega}(\omega)$. Let $\Delta$ be a ranked alphabet such that $\Delta \cap \Omega=\emptyset$ and $Y \subseteq X$. We define $I_{\Omega, \Delta}(Y)$ as the set of all $t \in T_{I(\Omega) \cup \Delta}(Y)$ where each index occurs at most once. Instead of $I_{\Omega, \Delta}(\emptyset)$, I will be writing $I_{\Omega, \Delta}$. The deindexing function $D$ removes all indices from a tree $t \in T_{I(\Omega) \cup \Delta}(Y)$. For a tree $t \in T_{I(\Omega) \cup \Delta}(Y), \operatorname{ind}(t)$ is the set of all indices occuring in t . Let $k \in \mathbb{N}$ and $t_{1}, \ldots, t_{k} \in T_{I(\Omega) \cup \Delta}(Y)$. Then, $D\left(t_{1} \ldots t_{k}\right)=D\left(t_{1}\right) \ldots D\left(t_{k}\right)$ and $\operatorname{ind}\left(t_{1} \ldots t_{k}\right)=\bigcup_{i \in[k]} i n d\left(t_{k}\right)$. For a string $s \in(I(\Omega) \cup \Delta)^{*}, D(s)$ and $\operatorname{ind}(s)$ are defined in the same way.

An LCFRS $/$ sDCP hybrid grammar is a tuple $G=(N, S,(\Gamma, \Sigma), P)$ where

- $N$ is an alphabet of nonterminals,
- $\Gamma, \Sigma$ are ranked alphabets of terminals with $\Gamma \subseteq \Sigma^{(0)}$,
- $S \in N$ is the initial nonterminal, and
- $P$ is a set of rules, described in the following.

Let $\Delta$ be the ranked alphabet $\Sigma \backslash \Gamma$, where for each $\delta \in \Delta, r k_{\Delta}(\delta)=$ $r k_{\Sigma}(\delta)$. Let $n, k, l, m, p, q \in \mathbb{N}, Y, Z \subseteq X, s_{1}, \ldots, s_{k} \in(\Gamma \cup Y)^{*}, t_{1}, \ldots, t_{l} \in$ $I_{\Gamma, \Sigma}(Z), i_{1}, \ldots, i_{p} \in I_{N, \emptyset}(Y), r_{1}=i_{1} \ldots i_{p}, i_{1}^{\prime}, \ldots, i_{q}^{\prime} \in I_{N \cup \Gamma, \Delta}(Z)$, and $r_{2}=$ $i_{1}^{\prime} \ldots i_{q}^{\prime}$. Each rule is of the form $\left[A\left(s_{1}, \ldots, s_{k}\right) \rightarrow r_{1}, A\left(t_{1}, \ldots, t_{l}\right) \rightarrow r_{2}\right]$ such that $D\left(A\left(s_{1}, \ldots, s_{k}\right)\right) \rightarrow D\left(r_{1}\right)$ has the form of an LCFRS rule and $D\left(A\left(t_{1}, \ldots, t_{l}\right)\right) \rightarrow$ $D\left(r_{2}\right)$ has the form of an sDCP rule. We also demand that each index couples two identical symbols. Let $P_{1}$ be the set of all $D\left(A\left(s_{1}, \ldots, s_{k}\right)\right) \rightarrow D\left(r_{1}\right)$ where $A\left(s_{1}, \ldots, s_{k}\right) \rightarrow r_{1}$ is the first component of a rule in P. $P_{2}$ is similarly defined for the second component of rules. We demand that $\left(N, S, \Gamma, P_{1}\right)$ is an LCFRS and $\left(N, S, \Sigma, P_{2}\right)$ is an sDCP. These two grammars are called the first and second component of the hybrid grammar.

In order to define the derivation relation, we need to define reindexing functions for terminals and nonterminals. The reason for this is that one rule can be applied multiple times during the derivation of a word. This can lead to a situation where, in a sentential form of the first or second component of a hybrid grammar, there are multiple occurrences of the same symbol with the same index. To avoid such a situation the indices need to be reassigned when applying a rule. For the nonterminal reindexing function we define a set $U \subseteq \mathbb{N}_{+}$ of existing indices. The nonterminal reindexing function $f$ replaces indices in each rule such that the new indices are not already contained in $U$. A terminal reindexing function replaces the indices at the terminals in the rule with the indices of the corresponding nonterminals in the sentential form.

We can now define the derivation relation as follows. We let

$$
\begin{aligned}
& {\left[s_{1}^{\prime \prime} \ldots s_{i_{s}}^{\prime \prime} A^{[\mathbf{u}}\left(s_{1}^{\prime}, \ldots, s_{k}^{\prime}\right) s_{i_{s}+1}^{\prime \prime} \ldots s_{j_{s}}^{\prime \prime}, t_{1}^{\prime \prime} \ldots t_{i_{t}}^{\prime \prime} A^{\underline{\mathrm{u}}}\left(t_{1}^{\prime}, \ldots, t_{k}^{\prime}\right) t_{i_{t}+1}^{\prime \prime} \ldots t_{j_{t}}^{\prime \prime}\right] \Rightarrow{ }_{G}^{u, g} } \\
& {\left[s_{1}^{\prime \prime} \ldots s_{i_{s}}^{\prime \prime} \cdot r_{1}^{\prime} \cdot s_{i_{s}+1}^{\prime \prime} \ldots s_{j_{s}}^{\prime \prime}, t_{1}^{\prime \prime} \ldots t_{i_{t}}^{\prime \prime} r_{2}^{\prime} t_{i_{t}+1}^{\prime \prime} \ldots t_{j_{t}}^{\prime \prime}\right] }
\end{aligned}
$$

for every $i_{s}, j_{s}, i_{t}, j_{t} \in \mathbb{N}$ (with $\left.i_{s} \leq j_{s}, i_{t} \leq j_{t}\right), s_{1}^{\prime \prime}, \ldots, s_{j_{s}}^{\prime \prime} \in I_{N \cup \Gamma, \emptyset}, t_{1}^{\prime \prime}, \ldots, t_{j_{t}}^{\prime \prime} \in$ $I_{N \cup \Gamma, \Delta}, s_{1}^{\prime}, \ldots, s_{k}^{\prime} \in I(\Gamma)^{*}, t_{1}^{\prime}, \ldots, t_{k}^{\prime} \in I_{\Gamma, \Delta}$, if:

- $\left[A\left(s_{1}, \ldots, s_{k}\right) \rightarrow r_{1}, A\left(t_{1}, \ldots, t_{l}\right) \rightarrow r_{2}\right] \in P$,
- $\exists U \subseteq \mathbb{N}$, such that $U=\operatorname{ind}\left(s_{1}^{\prime \prime} \ldots s_{i_{s}}^{\prime \prime} A^{\mathbf{u}}\left(s_{1}^{\prime}, \ldots, s_{k}^{\prime}\right) s_{i_{s}+1}^{\prime \prime} \ldots s_{j_{s}}^{\prime \prime}\right) \backslash\{u\}=$ $\operatorname{ind}\left(t_{1}^{\prime \prime} \ldots t_{i_{t}}^{\prime \prime} A^{\boxed{u}}\left(t_{1}^{\prime}, \ldots, t_{k}^{\prime}\right) t_{i_{t}+1}^{\prime \prime} \ldots t_{j_{t}}^{\prime \prime}\right) \backslash\{u\}$,
- there is a terminal reindexing function $g$ such that $g\left(s_{1}, \ldots, s_{k}\right)=\left(s_{1}^{\prime}, \ldots, s_{k}^{\prime}\right)$,
- $A\left(s_{1}^{\prime}, \ldots, s_{k}^{\prime}\right) \rightarrow r_{1}^{\prime}$ is obtained from $g\left(f_{U}\left(A\left(s_{1}, \ldots, s_{k}\right) \rightarrow r_{1}\right)\right)$ by replacing variables with strings in $I(\Gamma)^{*}$, and
- $A\left(t_{1}^{\prime}, \ldots, t_{k}^{\prime}\right) \rightarrow r_{2}^{\prime}$ is obtained from $g\left(f_{U}\left(A\left(t_{1}, \ldots, t_{k}\right) \rightarrow r_{2}\right)\right)$ by replacing variables with trees in $I_{\Gamma, \Delta}$.

The language accepted by an LCFRS/sDCP hybrid grammar G is the set of all hybrid trees $h=\left(\xi, \leq_{\xi}\right)$ with $[\operatorname{str}(\xi), \xi] \Rightarrow_{G}^{*}[\varepsilon, \varepsilon]$

Example 2.4. We can obtain a hybrid grammar that accepts the hybrid tree from Example 2.1 by combining the LCFRS from Example 2.2 and the sDCP from Example 2.3. I will only give the set $P$ of hybrid rules here.

$$
\begin{aligned}
\rho_{1}= & {\left[S\left(x_{2} x_{1} x_{3}\right) \rightarrow N P^{1}\left(x_{1}\right) V P^{2}\left(x_{2}, x_{3}\right), S\left(\mathbf{S}\left(x_{1} x_{2}\right)\right) \rightarrow N P^{1}\left(x_{1}\right) V P^{2}\left(x_{2}\right)\right] } \\
\rho_{2}= & {\left[V P\left(x_{3} x_{1}, x_{2}\right) \rightarrow V^{1}\left(x_{1}\right) N P^{2}\left(x_{2}\right) N P^{\sqrt{3}}\left(x_{3}\right),\right.} \\
& \left.V P\left(\mathbf{V P}\left(x_{1} x_{2} x_{3}\right)\right) \rightarrow V^{1}\left(x_{1}\right) N P^{2}\left(x_{2}\right) N P^{3}\left(x_{3}\right)\right] \\
\rho_{3}= & {\left[N P\left(x_{1} x_{2}\right) \rightarrow D e t^{1}\left(x_{1}\right), N^{2}\left(x_{2}\right), N P\left(\mathbf{N P}\left(x_{1} x_{2}\right)\right) \rightarrow D e t^{1]}\left(x_{1}\right) N^{2}\left(x_{2}\right)\right] } \\
\rho_{4}= & {\left[N P\left(\mathbf{s i e}^{1}\right) \rightarrow \varepsilon, N P\left(\mathbf{N P}^{1}\left(\mathbf{s i e}^{1}\right)\right) \rightarrow \varepsilon\right] } \\
\rho_{5}= & {\left[V\left(\mathbf{g a b}^{1}\right) \rightarrow \varepsilon, V\left(\mathbf{V}\left(\mathbf{g a b}^{1}\right)\right) \rightarrow \varepsilon\right] } \\
\rho_{6}= & {\left[\operatorname{Det}\left(\mathbf{D a s}^{1}\right) \rightarrow \varepsilon, \operatorname{Det}\left(\mathbf{D e t}^{1}\left(\mathbf{D a s}^{1}\right)\right) \rightarrow \varepsilon\right] } \\
\rho_{7}= & {\left[N\left(\mathbf{B u c h}^{1}\right) \rightarrow \varepsilon, N\left(\mathbf{N}\left(\mathbf{B u c h}^{1}\right)\right) \rightarrow \varepsilon\right] } \\
\rho_{8}= & {\left[N P\left(\mathbf{i h m}^{1}\right) \rightarrow \varepsilon, N P\left(\mathbf{N P}\left(\mathbf{i h m}^{1}\right)\right) \rightarrow \varepsilon\right] }
\end{aligned}
$$

The hybrid tree can be derived as follows (the words in the string are abbreviated by their first letter):

$$
\begin{aligned}
& {\left[S^{1]}\left(\mathbf{D}^{2} \mathbf{B}^{\sqrt[3]{3}} \mathbf{g}^{4} \mathbf{s}^{5} \mathbf{i}^{[6]}\right),\right.} \\
& \left.S^{1}\left(\mathbf{S}\left(\mathbf{N P}\left(\mathrm{~s}^{5}\right), \mathbf{V P}\left(\mathbf{V}\left(\mathrm{g}^{4}\right), \mathbf{N P}\left(\mathrm{i}^{6}\right), \mathbf{N P}\left(\operatorname{Det}\left(\mathbf{D}^{2}\right), \mathbf{N}\left(\mathbf{B}^{3}\right)\right)\right)\right)\right)\right] \\
& \Rightarrow{ }_{G}^{1]}, \rho_{1}\left[N P^{1}\left(\mathrm{~s}^{5}\right) V P^{7}\left(\mathbf{D}^{2} \mathbf{B}^{3} \mathrm{~g}^{\frac{4}{4}}, \mathrm{i}^{6}\right),\right. \\
& N P^{1}\left(\mathbf{N P}\left(\mathbf{s}^{5}\right)\right) V P^{7}\left(\mathbf{V P}\left(\mathbf{V}\left(\mathbf{g}^{4}\right), \mathbf{N P}\left(\mathbf{i}^{6}\right), \mathbf{N P}\left(\operatorname{Det}\left(\mathbf{D}^{2}\right), \mathbf{N}\left(\mathbf{B}^{[3}\right)\right)\right)\right] \\
& \Rightarrow{ }_{G}^{1}, \rho_{4}\left[V P^{7}\left(\mathbf{D}^{2} \mathbf{B}^{[3} \mathbf{g}^{4]}, \mathbf{i}^{6}\right),\right. \\
& V P^{7}\left(\mathbf{V P}\left(\mathbf{V}\left(\mathbf{g}^{4}\right), \mathbf{N P}\left(\mathbf{i}^{6}\right), \mathbf{N P}\left(\operatorname{Det}\left(\mathbf{D}^{2}\right), \mathbf{N}\left(\mathbf{B}^{3}\right)\right)\right)\right] \\
& \Rightarrow \frac{7}{G}, \rho_{2}\left[V^{1}\left(\mathbf{g}^{4}\right) N P^{8}\left(\mathbf{D}^{2} \mathbf{B}^{3}\right) N P^{9}\left(\mathbf{i}^{6}\right),\right. \\
& \left.V^{1}\left(\mathbf{V}\left(\mathbf{g}^{4}\right)\right) N P^{9}\left(\mathbf{N P}\left(\mathbf{i}^{6}\right)\right) N P^{8}\left(\mathbf{N P}\left(\operatorname{Det}\left(\mathbf{D}^{2}\right), \mathbf{N}\left(\mathbf{B}^{\frac{3}{3}}\right)\right)\right)\right] \\
& \Rightarrow \frac{11}{G}, \rho_{5}\left[N P^{8}\left(\mathbf{D}^{2} \mathbf{B}^{3}\right) N P^{9}\left(\mathbf{i}^{6}\right),\right. \\
& \left.N P^{9}\left(\mathbf{N P}\left(\mathbf{i}^{6}\right)\right) N P^{8}\left(\mathbf{N P}\left(\operatorname{Det}\left(\mathbf{D}^{2}\right), \mathbf{N}\left(\mathbf{B}^{3}\right)\right)\right)\right] \\
& \Rightarrow \frac{9}{G}, \rho_{8}\left[N P^{8}\left(\mathbf{D}^{2} \mathbf{B}^{3}\right), \quad N P^{8}\left(\mathbf{N P}\left(\operatorname{Det}\left(\mathbf{D}^{2}\right), \mathbf{N}\left(\mathbf{B}^{3}\right)\right)\right)\right]
\end{aligned}
$$

$$
\left.\begin{array}{l}
\Rightarrow \frac{11}{G}, \rho_{6}\left[N^{10}\left(\mathbf{B}^{3}\right), N^{10}\left(\mathbf{N}\left(\mathbf{B}^{3}\right)\right)\right] \\
\Rightarrow \frac{10}{G}, \rho_{7}
\end{array} \varepsilon, \varepsilon\right]
$$

Here we used the following reindexing functions:

| rule used | nonterminal reindexing | terminal reindexing |
| :---: | :---: | :---: |
| $\rho_{1}$ | $f_{\{2, \ldots, 6\}}(2)=7$ | $g$ identity |
| $\rho_{4}$ | $f_{\{2, \ldots, 7\}}$ identity | $g(1)=5$ |
| $\rho_{2}$ | $f_{\{2,3,4,6,7\}}(2)=8$ | $g$ identity |
| $\rho_{5}$ | $f_{\{2,3,4,6,7\}}(3)=9$ | $f_{\{2,3,6,8,9\}}$ identity |
| $\rho_{8}$ | $f_{\{2,3,6,8\}}$ identity | $g(1)=4$ |
| $\rho_{3}$ | $f_{\{2,3,8\}}(2)=10$ | $g(1)=4$ |
| $\rho_{6}$ | $f_{\{1,2,3,10\}}$ identity | $g$ identity |
| $\rho_{7}$ | $f_{\{3,10\}}$ identity | $g(1)=2$ |

### 2.2 Induction of hybrid grammars

Gebhardt et al. [5] formalize probabilistic hybrid grammars (already mentioned in [7]) by assigning probabilities to rules. Let $G=(N, S,(\Gamma, \Sigma), P)$ be a hybrid grammar, $A \in N$, and $P_{A} \subseteq P$ the set of all $\rho \in P$ where $A$ is the nonterminal in the left-hand sides of the first and second component of $\rho$. $G$ is proper if for all $B \in N, \sum_{\rho \in P_{B}} p(\rho)=1$, where $p(\rho)$ is the probability of $\rho$. We demand that a probabilistic hybrid grammar is proper.

In order to induce a hybrid grammar on a corpus of hybrid trees $\left(\xi, \leq_{\xi}\right)$ they define recursive partitionings as a way to add structural information to $\operatorname{str}(\xi)$.

### 2.2.1 Recursive Partitionings

Recursive partitionings were introduced by Nederhof and Vogler [7].
A recursive partitioning is a tree $\pi \in T_{P(\mathbb{N})}$ whose nodes are labeled with sets of natural number, such that

1. the root is labeled with $\{1, \ldots, n\}$ for some $n \in \mathbb{N}$,
2. all leaves are labeled with a set of size one,
3. the label of each non-leaf node is the union of the labels of its children,
4. the labels of the children of each non-leaf node are disjoint, and
5. each non-leaf node has at least two children.

Let $n, m \in \mathbb{N}$ with $n<m$. The span of $n$ and $m$, denoted by $\operatorname{span}(n, m)$, is the set $\{n, n+1, \ldots, m\}$.

Let J be the label of a node of a recursive partitioning. The fanout of J is the smallest number $k$ of sets $J_{i}$ such that $J=\bigcup_{i=1}^{k} J_{i}$ and for each $i \in[k]$, there are $n, m \in \mathbb{N}$, such that $J_{i}=\operatorname{span}(n, m)$. The fanout of a recursive partitioning is the maximal fanout of the labels of its nodes.

### 2.2.2 Extraction of a recursive partitioning from a hybrid tree

In order to obtain a recursive partitioning $\pi$ that reflects the structure of a hybrid tree $\left(\xi, \leq_{\xi}\right)$, Gebhardt et al. [5] introduce an extraction algorithm (Algorithm 6.2 in [5]).

Let $\Gamma, \Sigma$ be ranked alphabets, such that $\Gamma \subseteq \Sigma^{(0)}$, and $h=\left(\xi, \leq_{\xi}\right)$ a hybrid tree over $\Gamma$ and $\Sigma$. The algorithm replaces the label of each node whose label is in $\Gamma$ with a number according to the order imposed on these nodes by $\leq_{\xi}$. The label of each non-leaf node is replaced by the union of the numbers assigned to its children (and to itself, if its label is in $\Gamma$ as well). Non-leaf nodes whose labels have size one are removed.

Example 2.5. This is the hybrid tree from Example 2.1 and the recursive partitioning extracted from it.

### 2.2.3 Induction of a hybrid grammar from a hybrid tree and a recursive partitioning

For the induction of hybrid grammars, Gebhardt et al. [5] introduce algorithms for the induction of an LCFRS and an sDCP that each contains indices that couple the two grammars.

Algorithm 6.1 in [5] induces an LCFRS from a string $s$ with length $l$ and a recursive partitioning $\pi$ where the label of the root of $\pi$ is $[l]$. The labels of the nodes of $\pi$ become the nonterminals of the LCFRS. The algorithm creates one rule out of each node of the recursive partitioning. The label of the node is made the nonterminal in the left-hand side, while the labels of the children of that node become the nonterminals in the right-hand side. The variables in the left-hand side argument are ordered in a way that in a derivation step each terminal of $s$ is assigned to the corresponding nonterminal in the left-hand side. Corresponding means here that the nonterminal contains the number corresponding to the position of the terminal in $s$. For the leaves, the nonterminals in the left-hand side of the rule take one argument which is the terminal in $s$ that corresponds to the number in the nonterminal. The right-hand side of these rules is just $\varepsilon$.

Example 2.6. With the recursive partitioning from Example 2.5 and the string "Das Buch gab sie ihm", Algorithm 6.1 from [5] induces the following LCFRS: $G=(N, \Sigma, S, R)$, where

- $N=\{0\{1,2,3,4,5\}), 0\{4\}),(\{\{1,2,3,5\}),(\{3\}),(\{\{5\}), 0\{1,2\}), 0\{1\}),(\{\{2\})\}$,
- $\Sigma=\{B u c h$, sie $, i h m, g a b, D a s\}$,
- $S=(\{1,2,3,4,5\})$,
- $R=\left\{\rho_{1}, \ldots, \rho_{8}\right\}$ as specified in the following.

$$
\begin{aligned}
\rho_{1} & =(\{1,2,3,4,5\})\left(x_{2} x_{1} x_{3}\right) \rightarrow(\{4\})\left(x_{1}\right) 0\{1,2,3,5\} D\left(x_{2}, x_{3}\right) \\
\rho_{2} & \left.=(\{1,2,3,5\})\left(x_{3} x_{1}, x_{2}\right) \rightarrow(\{3\})\left(x_{1}\right)(\{5\})\left(x_{2}\right) 0\{1,2\}\right)\left(x_{3}\right) \\
\rho_{3} & =(\{1,2\})\left(x_{1} x_{2}\right) \rightarrow \operatorname{Det}\left(x_{1}\right) 0\{2\} D\left(x_{2}\right) \\
\rho_{4} & =(\{4\} D(\text { sie }) \rightarrow \varepsilon \\
\rho_{5} & =(\{3\} D(\text { gab }) \rightarrow \varepsilon \\
\rho_{6} & =(\{1\} D(\text { Das }) \rightarrow \varepsilon \\
\rho_{7} & =(\{2\} D(\text { Buch }) \rightarrow \varepsilon \\
\rho_{8} & =(\{5\} D(\text { ihm }) \rightarrow \varepsilon
\end{aligned}
$$

Notice that the nonterminal $(\{1,2,3,5\})$ has a fanout of two. This is because the label of the corresponding node in the recursive partitioning also has fanout two. Therefore, we can induce an LCFRS with a lower fanout by using a different recursive partitioning. This is desirable because a lower fanout leads to a lower parsing complexity.

Take, for example, the following recursive partitioning which has a fanout of one instead of two.
$\{1,2,3,4,5\}$
$\{5\}$

With it, the algorithm returns the following LCFRS which has a fanout of one. (I give only the rules of the LCFRS here):

$$
\begin{aligned}
& \rho_{1}=\left(\{1,2,3,4,5\} \emptyset\left(x_{2} x_{1}\right) \rightarrow\{\{5\}\rangle\left(x_{1}\right)(\{1,2,3,4\})\left(x_{2}\right)\right. \\
& \rho_{2}=(\{1,2,3,4\})\left(x_{2} x_{1}\right) \rightarrow 0\{4\} D\left(x_{1}\right)\left(\{1,2,3\} D\left(x_{2}\right)\right. \\
& \rho_{3}=\left(\{1,2,3\} \emptyset\left(x_{2} x_{1}\right) \rightarrow 0\{3\} D\left(x_{1}\right) \backslash\{1,2\} D\left(x_{2}\right)\right. \\
& \rho_{4}=0\{1,2\} \emptyset\left(x_{1} x_{2}\right) \rightarrow 0\{1\} \emptyset\left(x_{1}\right) \backslash\{2\} \emptyset\left(x_{2}\right) \\
& \rho_{5}=(\{4\})(\text { sie }) \rightarrow \varepsilon \\
& \left.\rho_{6}=\eta\{3\}\right\rangle(g a b) \rightarrow \varepsilon
\end{aligned}
$$

$$
\begin{aligned}
\rho_{7} & =(\{1\})(\text { Das }) \rightarrow \varepsilon \\
\rho_{8} & =(\{2\})(\text { Buch }) \rightarrow \varepsilon \\
\rho_{9} & =(\{5\})(\text { ihm }) \rightarrow \varepsilon
\end{aligned}
$$

Algorithm 6.5 in [5] induces an sDCP from a dependency structure $h=$ $\left(\xi, \leq_{\xi}\right)$ and a recursive partitioning $\pi$. It uses a construction similar to the algorithm for induction of LCFRS.

When inducing a grammar from a corpus of trees, the nonterminals produced from each tree are renamed in order to make rules and nonterminals less dependent on one specific tree. For this, Nederhof and Vogler [7, page 1376] introduce strict and child labeling as naming strategies. These can be used in combination with POS, DEPREL, and POS+DEPREL labeling.

## 3 The algorithm for the transformation of recursive partitionings

Gebhardt et al. [5] introduce an algorithm for the transformation of recursive partitionings, such that an arbitrary recursive partitioning is transformed into a recursive partitioning with a fanout less than or equal to a given value k (Algorithm 6.3 in [5]). The goal is to obtain a recursive partitioning that has the required fanout (to lead to a grammar with lower parsing complexity) but also retains the structure of the original recursive partitioning as far as possible. I slightly adapted this algorithm to fit my definition of recursive partitionings without s-terms in Algorithm 1.

The algorithm takes a recursive partitioning $\pi=J\left(\pi_{1}, \ldots, \pi_{n}\right)$, where $J$ is the label of the root and $\pi_{1}, \ldots, \pi_{n}$ are the subtrees of the root. It performs a search among the positions of $\pi$ until it finds a $p \in \operatorname{pos}(\pi)$ such that the sets $\pi(p)$ and $J \backslash \pi(p)$ each have a fanout less than or equal to $k$ (line 5). Such a position always exists ([5, page 29]).

When the algorithm has found such a $p \in \operatorname{pos}(\pi)$, it creates a new tree $\pi^{\prime \prime}$ by removing all elements of $\pi(p)$ from $\pi$ (line 7). For this, the function REMOVE (line 10-line 23) is called. It then obtains the transformed recursive partitioning by recursively transforming $\left.\pi\right|_{p}$ and $\pi^{\prime \prime}$ and using them as subtrees (line 8).

In line 5, Gebhardt et al. [5] choose $p$ according to a breadth-first search. However, it is also possible to use another strategy for choosing $p$. My task is to implement different strategies for choosing $p$ and to compare the grammars induced with the recursive partitionings obtained with these strategies.

## 4 Implementation

For their implementation of the induction of hybrid grammars, Gebhardt et al. [5] implemented Algorithm 1 with right-to-left breadth-first search for line 5. Recursive partitionings are implemented as tuples consisting of the label of the

```
Algorithm 1 Transformation of a recursive partitioning
Require:
    a recursive partitioning \(\pi\)
    a maximal fanout \(k \in \mathbb{N}\)
Ensure: a recursive partitioning with fanout \(\leq k\)
    function TRANSFORM \(\left(\pi=J\left(\pi_{1}, \ldots, \pi_{n}\right), k\right)\)
        if \(|J|=1\) then
            return \(\pi\)
        end if
        \(p \leftarrow\) breadth-first search for some \(p \in \operatorname{pos}(\pi) \backslash\{\varepsilon\}\)
            \(\hookrightarrow\) such that \(\pi(p)\) and \(J \backslash \pi(p)\) each have fanout \(\leq k\)
        \(\left.\pi^{\prime} \leftarrow \pi\right|_{p}\)
        \(\pi^{\prime \prime} \leftarrow \operatorname{Remove}(\pi, \pi(p))\)
        return \(\mathrm{J}\left(\right.\) TRANSFORM \(\left(\pi^{\prime}, k\right)\), TRANSFORM \(\left.\left(\pi^{\prime \prime}, k\right)\right)\)
    end function
    function REMOVE \(\left(\pi=J\left(\pi_{1}, \ldots, \pi_{k}\right), I\right)\)
                                    \(\triangleright\) Removes all occurences of members of the set I from \(\pi\).
    \(J^{\prime} \leftarrow J \backslash I\)
    \(j \leftarrow 0\)
    for \(i=1, \ldots, k\) do
        \(\pi^{\prime} \leftarrow \operatorname{REmove}\left(\pi_{i}, \mathrm{I}\right)\)
        if \(\pi^{\prime}(\varepsilon)=J^{\prime}\) then
            return \(\pi^{\prime}\)
        else if \(\pi^{\prime}(\varepsilon) \neq \emptyset\) then
            \(j++\)
            \(\pi_{j}^{\prime} \leftarrow \pi^{\prime}\)
        end if
    end for
    return \(J^{\prime}\left(\pi_{1}^{\prime}, \ldots, \pi_{j}^{\prime}\right)\)
    end function
```

root and a list of the children of the root, which are recursively implemented in the same way. I adapt this implementation to include transformations

- with left-to-right breadth-first search,
- with choosing $p$ such that $p=\operatorname{argmax}_{p \in \operatorname{pos}(\pi)}|\pi(p)|$ (meaning such that $\pi$ at position $p$ has the label with the most elements),
- with choosing $p$ randomly, and
- with choosing $p$ such that no new nonterminals are added if possible. If that is not possible, $p$ is chosen according to one of the other strategies.

The functions implementing the transformations can be found in the file lcfrs-sdcp-hybrid-grammars/decomposition.pyx. For running the experiment, one needs to install a number of prerequisites, for which there is a wiki by Gebhardt and Teichmann [4]. Then on needs to execute the file lcfrs-sdcp-hybrid-grammars/playground/play_recursive_partitioning.py. Assuming one is in the playground directory, it can be called with PYTHONPATH=.. python2.7 play_recursive_partitioning.py.

### 4.1 Command-line options

I have implemented command line options for play_recursive_partitioning.py that determine the transformation strategy and hyperparameters. Some option can be passed multiple arguments separated by whitespace. These are -s, -l, $-t,-f,-n$, and $-r$. A call could look like this: PYTHONPATH=. . python2.7 play_recursive_partitioning.py -s rtl argmax -l child -f 23. Table 1 provides an overview over the command line options.

### 4.2 Output file

The output is saved in the file results.txt. For each combination of transformation strategy, labeling strategy, and maximal fanout, the file contains a number of lines. These lines contain:

- the current strategy, labeling, and fanout,
- the number of nonterminals and rules of the induced grammar, and
- the average number of derivation trees per sentence and the maximal number of derivation trees of any sentence.
- The next three lines contain labeled and unlabeled attachment scores with and without punctuation.
- The last line shows the parse time.

Table 1: Command line options

| Option | Meaning | Possible choices | Default |
| :---: | :---: | :---: | :---: |
| -s | strategy for choosing p | - rtl for right-to-left breadth-first search <br> - ltr for left-to-right breadth-first search <br> - argmax for choosing $p=$ $\operatorname{argmax}_{p \in \operatorname{pos}(\pi)}\|\pi(p)\|$ <br> - random for random choice <br> - nnont for no new nonterminals if possible | rtl |
| -1 | labelling strategy | strict, child | strict |
| -t | also labelling strategy | pos, deprel, pos+deprel | pos |
| -f | maximal fanout |  | 1 |
| -n | fallback strategy for no-newnonterminals strategy | rtl, ltr, random, argmax | rtl |
| -r | random seed for random choice |  | 1 |
| -c | language | polish, german | german |
| -d | whether or not to count derivation trees | yes, no, y, n | yes |
| -q | use shortened version of german dev-corpus | yes, no | yes |
| -e | whether or not to determine attachment scores and parse times | yes, no | yes |

The numbers for the derivation trees and/or the attachment scores and the parse time can be missing, if play_recursive_partitioning.py was called with the respective command-line options or if the RAM was insufficient. If the RAM is insufficient for counting the derivation trees, the file also does not show the attachment scores and parse times since these are determined later in play_recursive_partitioning.py. In that case play_recursive_ partitioning.py needs to be run again with the option '-d no'.

### 4.3 Common elements of the transformation functions

The functions implementing the various strategies share common elements which were introduced in the implementation by Gebhardt et al. [5]. I will give an overview over these common elements before describing the individual strategies.

All of the functions take a recursive partitioning (called part) and the maximal fanout (called fanout) as arguments. They search for a subtree of part such that the label of the root of that subtree (saved in the variable subroot) and the label of the root of part, with the elements of subroot removed, have a fanout less than or equal to fanout. I will refer to that condition as the target condition.

To do that, the functions first copy the children of the root of part into the list agenda and perform a breadth-first search on agenda. The label of the root of part is held in the variable root. For each element of agenda (child1) they check, whether the label of the root of child1 (subroot) and root fulfill the target condition.

### 4.4 Right-to-left breadth-first search

This strategy was implemented by Gebhardt et al. [5]. The implementation can be found in the function fanout_limited_partitioning() from lines 76-101. Like the functions for the other transformation strategies it performs a breadthfirst search over agenda, but before that, it reverses agenda for right-to-left branching (line 85).

If the target condition is fulfilled, the function restrict_part() is called, which deletes all elements of subroot from part (line 94, corresponding to line 7 of Algorithm 1). Then fanout_limited_partitioning_left_to_right() is called recursively on child1 and the result of restrict_part(), yielding transformed trees which are respectively saved in child1_restrict and child2_restrict. The function then returns a recursive partitioning with root as the label of its root and with child1_restrict and child2_restrict as children of its root (lines 95-97, corresponding to line 8 of Algorithm 1).

If the target condition is not fulfilled, the children of child1 are, in right-to-left order, added to the end of the queue for the breadth-first search (line 99).

### 4.5 Left-to-right breadth-first search

This strategy is implemented in the function fanout_limited_partitioning _left_to_right() (lines 104-130). It works almost the same as the implementation for right-to-left breadth-first search, except that the lists children and subchildren are not reversed when added to agenda (lines 114 and 128).

### 4.6 Choice of $p=\operatorname{argmax}_{p \in \operatorname{pos}(\pi)}|\pi(p)|$

This strategy is implemented in the function fanout_limited_partitioning _argmax () (lines 133-165). Like the other functions it performs a breadthfirst search through the subtrees of part, however, instead of using the first solution, all positions are checked. If child1 fulfills the target condition, the function determines, whether one of the previous possible solutions is better than child1. For this strategy, better means that subroot has more elements than argroot, which is the label of the root of the previous best solution. If so, child1 is copied into the variable argmax (lines 144 and 156-157). That way argmax holds the subtree with the most elements in the label of its root. After having searched through all subtrees, the function calls itself recursively on argmax to create the transformed partitioning (lines 161-165).

### 4.7 Random Choice

This strategy is implemented in the function fanout_limited_partitioning _random_choice() (lines 343-373). Like the previous functions, it performs a breadth-first search among the subtrees of the recursive partitioning. If it finds one that fulfills the target condition (line 360), the function adds it to the list possibleChoices (lines 352 and 361). After all items in agenda have been processed, an element from possibleChoices is randomly selected (line 366) and then used to create the transformed partitioning (lines 369-373).

A random seed can be set through the command line in order to ensure repeatability of the experiments.

### 4.8 No new nonterminals

In this strategy, $p \in \operatorname{pos}(\pi)$ is chosen, such that it does not require a new nonterminal if such a $p$ exists. The idea behind this strategy is that $p$ could be chosen in a way that minimizes the number of nonterminals and/or rules of the resulting grammar. However, since the number of nonterminals/rules also depends on the recursive processing of the children and the processing of the other trees in the corpus, one needs to use a simplified approach.

This strategy is implemented in the function fanout_limited_partitioning _no_new_nont () (lines 169-213). It takes four extra arguments besides part and fanout. These are the current tree in the corpus (tree), for which the recursive partitioning is to be transformed, the previously generated nonterminals of the hybrid grammar (nonts), the nonterminal labelling strategy currently being used (nont_labelling), and the strategy to be used as fallback (fallback).

It performs a left-to-right breadth-first search on part. If it finds a subtree that fulfills the target condition (line 189), it also checks, whether subroot requires a new nonterminal (lines 190-198). If so, the function continues to search for a subtree which does not require a new nonterminal. If not, the subtree is used to create the transformed recursive partitioning (lines 202-205).

It is possible (and in the case of the first tree in the corpus inevitable) that all positions in part require a new nonterminal. In that case, the breadth-first search will not return a subtree of part to use for the transformation. Therefore the function then calls a fallback function (depending on the fallback parameter). These functions (fallback_rtl(), fallback_ltr(), fallback_argmax (), fallback_random () ) (lines 215-339) each work like their counterpart for the respective strategy, except that they call fanout_limited_partitioning_no_new _nont () for the recursive transformation of the subtrees instead of themselves.

## 5 Experiments

In this section, I show experimental results for the training of hybrid grammars with the various transformation strategies.

I ran most of the experiments on a computer with a 2.5 GHz Intel Core i5-7200U CPU and 8GB of RAM. For some experiments, the RAM was not sufficient. I ran those on a server with 32 GB RAM (capped at 15 GB ) and two Dual-Core AMD Opteron(tm) Processor 2224 SE CPUs, which had a clock rate of 1 GHz and 3.2 GHz , respectively. Therefore, the parse times for these experiments cannot be compared to the other results. They are marked in yellow in the table for parse times. For some experiments even the higher RAM was not sufficient, therefore, the table entries for these read "insuff. RAM".

For the no-new-nonterminals strategy, I list the results for different fallback strategies in separate columns.

For the random-choice strategy (and no-new-nonterminals with random choice as fallback) I ran three experiments with random seeds 1, 10, and 20. The results given here are the arithmetic mean of these experiments.

As terminal labeling strategy, I used POS for all experiments.
The first three columns in every table show the used nonterminal labeling strategy (strict or child and POS, DEPREL or POS+DEPREL) and the maximal fanout.

I use the same parsers as Gebhardt et al. [5]. For LCFRS parsing with maximal fanout one this is the OpenFST framework ([1]) with python bindings by Gorman [6]. For LCFRS parsing with a higher maximal fanout this is an LCFRS parser by Angelov and Ljunglöf [2], which is part of the Grammatical Framework ([8]).

Since Gebhardt et al. [5] did not find any grammar to have a fanout higher than four in their experiments, I did not include transformations for maximal fanout four or higher in my experiments.

In each table, the best entry is marked in green and in italics and the worst entry in red and bold. For the tables for the parse times, the marked results are
the best and worst results not computed on the server.
In the following sections I will be using abbreviations for the strategies.

- rtl for right-to-left breadth-first search
- ltr for left-to-right breadth-first search
- argmax for choosing $p$ such that $p=\operatorname{argmax}_{p \in \operatorname{pos}(\pi)}|\pi(p)|$
- random for choosing $p$ randomly
- nnont (fallback) for choosing $p$ sucht that no new nonterminal is created if possible. fallback stands for the abbreviation of the respective fallback strategy

### 5.1 Criteria

In this section, I will give an overview over the criteria according to which I compared the transformation strategies.

The number of nonterminals and rules in the induced grammar influences the parsing complexity. Therefore, a smaller number of nonterminals and rules is better.

The number of derivation trees for a sentence in the corpus indicates the ambiguity of the grammar. If the number is high, there are more ways to syntactically interpret the sentence. This can make semantic analysis of a sentence harder. Therefore, smaller numbers are better as well.

The unlabeled attachment score is the percentage of words for which the string parser found the correct HEAD, meaning the parent of that word in a dependency structure. The labeled attachment score also takes into account whether the parser found the correct label for that word (according to the terminal labeling strategy). For attachment scores, higher numbers are better since they mean that more words were correctly placed in relation to the grammatical structure of the sentence.

The parse time here is the time that was necessary for the string parser to parse the corpus and calculate the attachment scores.

### 5.2 Corpora

I am using corpora in the conll format from the SPMRL Shared Task [9]. Specifically, I use the German and the Polish Predicted training corpora for training of the grammars and counting of the number of derivation trees per sentence. For calculating the attachment scores and measuring the parse times, I used the development corpora. I shortened the German development corpus to the length of the Polish corpus in order to make parse times comparable. This is done by the script smallCorpus.py.

### 5.3 Number of nonterminals and rules

The results for random and nnont (random) were rounded to whole numbers.

In general, the strategies rtl and ltr produce the lowest number of nonterminals. For the German corpus, ltr is often slightly better than rtl, especially for strict labeling. The strategies random and nnont (random) lead in all but one case to the highest numbers. The reason for this is that with rtl and ltr, the recursive partitionings of similar hybrid trees are transformed in a similar way, whereas with random they can result in very different transformed partitionings which in turn lead to more different nonterminals.

The nnont strategies lead to higher numbers of nonterminals than the corresponding fallback strategies, with the exception of child labeling with fanout one for fallback rtl, ltr and with any fanout for fallback argmax. In these cases the numbers for nnont are between $7 \%$ and $66 \%$ lower than for the fallback strategies.For the German corpus, the strategies nnont (rtl), nnont (ltr) and nnont (argmax) lead to the overall lowest numbers for child labeling with maximal fanout one. For nnont (random), the numbers with child labeling are also better than with strict labeling, although they are higher than the numbers for random in all but one case. The reason for these observations is presumably that with child labeling, different nodes in recursive partitionings are assigned the same label. This makes it more likely that a node results in a nonterminal
that already exists.
For the Polish corpus, the different maximal fanouts do not lead to different results for the strategies ltr, rtl and their corresponding nnont strategies. For argmax, random and nnont (random) a higher maximal fanout leads to more nonterminals. This is due to the fact that, with a higher fanout, there are more nodes in a recursive partitioning that fulfill the target condition and could be randomly chosen or have the longest label. Therefore, there are more possibilities to transform recursive partitionings, which leads to more nonterminals. Interestingly, for nnont (argmax) the maximal fanout has no influence on the number of nonterminals. For the German corpus, the results are similar, except that the number of nonterminals is lower for fanouts two and three than for fanout one for the strategies rtl and ltr.

The German corpus leads to a higher number of nonterminals than the Polish corpus, depending on the strategy and the hyperparameters between $39 \%$ and $337 \%$ higher.

Similar observations can be made by considering the number of rules.
Table 4: Number of rules - Polish

### 5.4 Number of derivation trees

For random and nnont (random) both the average and the maximal number of derivation trees varied widely for the different random seeds. I, therefore, include both the arithmetic mean and the median for the results of these strategies.

### 5.4.1 Average number of derivation trees

Most of the numbers in these tables were rounded to two decimal places. In the polish table, I did not round the numbers in the columns ltr and rtl, because for some of these their difference to one would otherwise not have been visible.

### 5.4.2 Maximal number of derivation trees

The results for random and nnont (random) were rounded to whole numbers, since they are the average of three different runs.
Table 6：Average number of derivation trees－Polish

|  | 获 |  |  |  |  |  |  |  |  | 䓓 |  |  |  |  |  |  |  |  |

The strategies rtl and ltr lead to the grammars with the lowest ambiguity. For the Polish corpus, the average number of derivation trees is only in five cases for ltr and three cases for rtl higher than one. All of these eight cases are for maximal fanout one. The strategies random and nnont (random) lead to the highest numbers of parse trees. For these two strategies, there are large differences between the labeling strategies with POS+DEPREL leading to results that are orders of magnitude lower than the results for either POS or DEPREL labeling.

The average number of derivation trees for the nnont strategies is often higher than that of the corresponding fallback strategies. Exceptions from this are the argmax and nnont (argmax) strategies where nnont (argmax) results in a lower average number in most cases (in 14 out of 18 cases for the Polish corpus and in 16 out of 18 cases for the German corpus), especially with child labeling.

For argmax, a maximal fanout higher than one leads in most cases to more derivation trees (for the German corpus, fanout two always leads to a higher number than fanout three). For nnont (argmax), ltr, rtl, and their respective nnont strategies, the maximal fanout has no influence on the average number of derivation trees, for the Polish corpus. For the German corpus, a higher fanout leads to a higher ambiguity for ltr and rtl. For random and nnont (random) a higher maximal fanout leads to a lower average number of derivation trees.

The numbers for the German corpus are in all but four cases higher than the numbers for the Polish corpus.

Similar observations can be made for the maximum number of derivation trees, except that argmax and nnont (argmax) do not show as much of a difference with strict labeling.

For the Polish corpus, almost all the maximal numbers of derivation trees for nnont with fallback strategies rtl, ltr and argmax are powers of two, with only one exception.

### 5.5 Labelled attachment score

The results for random and nnont (random) were rounded to two decimal places, since the individual results for the different random seeds had the same accuracy.

Since the observations for the Labelled Attachment Score and the Unlabelled Attachment Score are similar with and without punctuation, I put the tables for the LAS with punctuation and all tables for the UAS in Appendix appendix A. The difference is that the UAS is higher than the LAS.

random almost always results in the lowest labeled attachment score, however, nnont (random) results in much higher labeled attachment scores and the highest of all strategies with POS and POS+DEPREL labeling.

The other results are close together with the exception of the nnont strategies with fallback rtl, ltr and argmax for strict/POS and strict/POS+DEPREL labeling. For these combinations, the values for fanout one are lower than the corresponding values of the fallback strategies and also lower than the values for maximal fanouts two and three. nnont (argmax) results in higher values than argmax for child/POS and child/POS+DEPREL labeling and maximal fanouts two and three.

For random a higher maximal fanout leads to a lower score. random with strict/POS + DEPREL labeling and maximal fanout three leads to the lowest score overall.

Both corpora lead to these observations, however, they sometimes differ in their scores depending on the labeling strategy.

|  |  | 3 | 18.59 | 8.93 | 15.56 | 12.35 | 12.12 | 11.94 | 24.63 | 9.51 |

ltr leads to the shortest parse times for maximal fanouts two and three. For maximal fanout one, the results for the strategies are close together, except for random and nnont (random), which lead to longer parse times. nnont (random) results always in the longest parse time. random usually leads to parse times only slightly shorter than nnont (random). The exception from this is strict/POS + DEPREL labeling where random leads to parse times that are almost as short as the times for ltr (up to $43 \%$ longer compared to up to $4003 \%$ longer for other labeling strategies).
nnont (rtl) and nnont (argmax) result in shorter parser than times rtl and argmax for maximal fanouts two and three. nnont (ltr) results in longer parse times than ltr for child labeling with maximal fanouts two and three.

The parse times for fanout two and three are longer than for fanout one,

wich is at least partially due to the different parsers. The only exceptions from this occur for DEPREL labeling in the Polish corpus. This is unclear for the German corpus since for child/DEPREL labeling and fanouts two and three, the RAM was insufficient in all but one case.

Induction using the German corpus leads to longer parse times than using the Polish corpus.

### 5.7 Conclusions

Considering all criteria, ltr produces the overall best results. While nnont (random) often leads to a higher LAS, it also leads to considerably longer parse times and a higher ambiguity. rtl leads to results similar to the ones of ltr with the exception of parse time for maximal fanouts two and three. random leads generally to worse results than most other strategies. The nnont strategies only minimize the number of nonterminals under specific circumstances and seem to work better for German than for Polish.

Some further questions that remain are

- Is there a better strategy for minimizing the number of nonterminals?
- How do the various transformation strategies compare to directly extracted recursive partitionings?
- Since both Polish and German have a relatively free word order, it would be interesting to see to what results the transformation strategies lead in languages with strict word order, such as English.

## Acknowledgement

I would like to thank Markus Teichmann for guiding me through this process, proofreading my drafts, and giving me advice.
